

## Design Procedure for Stable Suboptimal Fixed-Lag Smoothers

BRIAN D. O. ANDERSON, FELLOW, IEEE, AND  
HOANG B. DOAN

*Abstract*—A procedure is presented for designing stable suboptimal fixed-lag smoothers for the continuous-time linear Gaussian problem. Apart from incorporating an ideal delay, the smoothers are finite-dimensional. The design procedure involves the approximation by a very straightforward procedure of a matrix impulse response of compact support by a matrix impulse response with a rational and stable Laplace transform. The approximation procedure involves studying the pole-zero pattern of transfer functions derivable from the transfer function matrix being approximated.

### I. INTRODUCTION

For the linear Gaussian problem, it is well known that fixed-lag smoothing offers the possibility of achieving significantly lower error covariances than normal filtering, which is equivalent to smoothing with zero lag [1], [2]. It is perhaps less well known that difficulties often arise in implementing continuous-time fixed-lag smoothers since optimal fixed-lag smoothers are infinite-dimensional and are likely to be unstable [3].

Several techniques for eliminating these difficulties have been proposed; see, e.g., [4]–[6]. In this paper, we explore in more detail one of the schemes suggested in [6] for obtaining a suboptimal, stable fixed-lag smoother which is finite-dimensional, save for the inclusion of a delay. The scheme is applicable only when all processes are stationary.

### II. THE SMOOTHER EQUATION

Suppose that the signal model is of the usual type

$$\dot{x} = Fx + Gw, \quad z = H'x + v \quad (1)$$

Manuscript received September 1, 1976; revised July 11, 1977. Paper recommended by Y. Bar-Shalom, Chairman of the Stochastic Control Committee. This work was supported by the Australian Research Grants Committee.

The authors are with the Department of Electrical Engineering, University of Newcastle, New South Wales, Australia.

with  $\text{Re}\lambda_i(F) < 0$ , with the signal model operating from  $-\infty$ , and with  $[w' \ v']$  a zero-mean Gaussian process with

$$E \left\{ \begin{bmatrix} w(t) \\ v(t) \end{bmatrix} \begin{bmatrix} w(s) & v(s) \end{bmatrix} \right\} = \begin{bmatrix} Q & 0 \\ 0 & R \end{bmatrix} \delta(t-s) \quad (2)$$

where  $R$  is nonsingular. (The case of correlated  $w(\cdot)$  and  $v(\cdot)$  can also be handled.)

Let  $\Sigma$  be the unique nonnegative definite solution of

$$\Sigma F' + F \Sigma - \Sigma H R^{-1} H' \Sigma + G Q G' = 0. \quad (3)$$

Let  $\hat{x}(t|t)$  be the state estimate of  $x(t)$  provided at time  $t$  by the Kalman filter; let  $\nu(t) = z(t) - H' \hat{x}(t|t)$  denote the filter innovations process; and let  $\bar{F} = F - KH'$  where  $K$  is the Kalman filter gain. Then the fixed-lag smoothed estimate  $\hat{x}(t|t+\Delta) = E[x(t)|z(s), s < t+\Delta]$  is given by [7]

$$\hat{x}(t|t+\Delta) = \hat{x}(t|t) + \Sigma \int_0^\Delta \left[ \exp \bar{F}'(\Delta - \tau) \right] H R^{-1} \nu(t+\Delta - \tau) d\tau. \quad (4)$$

The error covariance of the smoothed estimate defined as

$$\Sigma(t|t+\Delta) = E \{ [x(t) - \hat{x}(t|t+\Delta)][x(t) - \hat{x}(t|t+\Delta)]' \}$$

is given by

$$\Sigma(t|t+\Delta) = \Sigma(t|t) - \Sigma(t|t) \int_t^{t+\Delta} \left[ \exp \bar{F}'(\Delta - \tau) \right] H R^{-1} H' \left[ \exp \bar{F}(\Delta - \tau) \right] d\tau \Sigma(t|t).$$

A delay line can be used to store  $\hat{x}(t|t)$  for a time  $\Delta$ . The second contribution to  $\hat{x}(t|t+\Delta)$  can be obtained by passing  $H R^{-1} \nu(\cdot)$  through a linear system with impulse response

$$M(t) = \Sigma \exp \bar{F}'(\Delta - t) \quad 0 \leq t \leq \Delta \\ = 0 \quad \text{elsewhere} \quad (5)$$

for which the associated Laplace transform is

$$\mathfrak{M}(s) = \Sigma [sI + \bar{F}']^{-1} [e^{\bar{F}'\Delta} - e^{-s\Delta} I]. \quad (6)$$

Observe that  $M(t)$  has compact support; as a consequence of a standard result of Laplace transform theory,  $\mathfrak{M}(s)$  is analytic for all finite  $s$ .

### III. SUBOPTIMAL SMOOTHER

It is suggested in [6] that a suboptimal smoother can be obtained by approximating (6) by a rational transfer function matrix with all poles in  $\text{Re}[s] < 0$ . Our purpose here is to explain how such an approximation may be undertaken.

To keep matters simple, assume that  $\bar{F}$  is diagonalizable. Let

$$\bar{F} = T \Lambda T^{-1}$$

with

$$\Lambda = \text{diag} \left\{ \lambda_1, \dots, \lambda_k, \begin{bmatrix} \alpha_1 & -\beta_1 \\ \beta_1 & \alpha_1 \end{bmatrix}, \dots, \begin{bmatrix} \alpha_j & -\beta_j \\ \beta_j & \alpha_j \end{bmatrix} \right\}.$$

One can check that

$$T' \Sigma^{-1} \mathfrak{M}(s) (T')^{-1} = \text{diag} \left\{ l_1(s), \dots, l_k(s), \begin{bmatrix} c_1(s) & -d_1(s) \\ d_1(s) & c_1(s) \end{bmatrix}, \dots, \begin{bmatrix} c_j(s) & -d_j(s) \\ d_j(s) & c_j(s) \end{bmatrix} \right\} \quad (7)$$

where

Fig. 1. Zero plot for  $l_i(s)$ .

$$l_i(s) = \frac{e^{\lambda_i \Delta} - e^{-s\Delta}}{s + \lambda_i} \quad (8)$$

$$\begin{bmatrix} c_k(s) & -d_k(s) \\ d_k(s) & c_k(s) \end{bmatrix} = \begin{bmatrix} s + \alpha_k & \beta_k \\ -\beta_k & s + \alpha_k \end{bmatrix}^{-1} \begin{bmatrix} e^{\alpha_k \Delta} \cos \beta_k \Delta - e^{-s\Delta} & e^{\alpha_k \Delta} \sin \beta_k \Delta \\ -e^{\alpha_k \Delta} \sin \beta_k \Delta & e^{\alpha_k \Delta} \cos \beta_k \Delta - e^{-s\Delta} \end{bmatrix} \quad (9)$$

Evidently, the task of approximating  $\mathfrak{M}(s)$  is equivalent to the task of approximating  $l_i(s)$ ,  $c_k(s)$ , and  $d_k(s)$ . Observe that  $l_i(s)$  is effectively defined by one parameter; then one has a one-parameter family of approximation problems to solve. On the other hand,  $c_k(s)$  and  $d_k(s)$  are governed effectively by two parameters.

We consider now the approximation of  $l_i(s)$ ,  $c_k(s)$ , and  $d_k(s)$ .

### IV. APPROXIMATION OF $l_i(s)$

It is easily checked that  $l_i(s)$  has no poles and an infinite number of zeros. Further, save for a missing zero on the real axis, these zeros are uniformly spaced on a line parallel to the imaginary axis; see Fig. 1.

If one plots the amplitude response  $|l_i(j\omega)|$  as a function of  $\omega$ , the response is roughly flat up to a certain frequency, and then falls off at 6 dB/octave. This suggests that one should approximate  $l_i(s)$  by a rational transfer function  $\bar{l}_i(s)$  determined in the following way:

1) The zeros of  $\bar{l}_i(s)$  coincide with those zeros of  $l_i(s)$  affecting the passband response, while those zeros remote from values of  $j\omega$  in the passband are discarded; thus, the zero set of  $l_i(s)$  is truncated to yield the zeros of  $\bar{l}_i(s)$ . (The possibility of truncating the zero pattern of  $l_i(s)$  was suggested by Prof. Ian Rhodes.)

2) The poles of  $\bar{l}_i(s)$  are chosen in the left half-plane (for stability) to be one greater in number than the number of zeros [to ensure the same high-frequency roll-off of  $l_i(s)$  and  $\bar{l}_i(s)$ ] and in a Butterworth [8] configuration on a radius significantly larger than the 3 dB frequency of  $l_i(j\omega)$  [thereby ensuring that their presence has little or no effect on the behavior of  $\bar{l}_i(s)$  in the passband].

3) The dc gain of  $\bar{l}_i(s)$  is chosen to coincide with that of  $l_i(s)$ .

A typical pole-zero plot for  $\bar{l}_i(s)$  is shown in Fig. 2.

### V. APPROXIMATION OF $c_j(s)$ AND $d_j(s)$

It turns out that one cannot vary the approach for approximating  $l_i(s)$  to cope with the separate approximation of  $c_k(s)$  and  $d_k(s)$ . One can, however, seek to approximate  $c_k(s)$  and  $d_k(s)$  simultaneously. A little

Fig. 2. Typical pole-zero plot for  $\bar{l}_i(s)$ .

manipulation using (9) reveals that

$$c_k(s) \pm jd_k(s) = \frac{1}{(s + \alpha_k) \pm j\beta_k} [e^{(\alpha_k \pm j\beta_k)\Delta} - e^{-s\Delta}]. \quad (10)$$

There are no poles; the zero patterns are shown in Fig. 3, and are like that of  $l_i(s)$ , save that they are not symmetrically located with respect to the real axis.

It is obvious that we can approximate  $c_k(s) + jd_k(s)$  and  $c_k(s) - jd_k(s)$  in exactly the same way as  $l_i(s)$  provided that

1) We allow for the zero off-set distance  $\pm\beta$  from the real axis by shifting all poles and zeros of the approximant up or down by the same offset;

2) We allow the scaling constant used to make the true function and the approximant agree at  $\omega=0$  to be a complex constant.

Denote the approximants by  $\gamma_+(s)$  and  $\gamma_-(s)$ ; they are rational functions with complex coefficients. Clearly, it is natural, having found  $\gamma_+(s)$ , to arrange for  $\gamma_-(s)$  to have as its poles and zeros the reflections in the real axis of the poles and zeros of  $\gamma_+(s)$ , while also by construction,  $\gamma_+(0) = \gamma_-^*(0)$ . Thus, if  $\gamma_+(s) = p(s)/q(s)$  for polynomial  $p(\cdot)$  and  $q(\cdot)$ , then  $\gamma_-(s) = p^*(s)/q^*(s)$  where the superscript asterisk denotes conjugation of coefficients. Then, since  $2c_k(s) = [c_k(s) + jd_k(s)] + [c_k(s) - jd_k(s)]$ , it is logical to take as the approximation  $\bar{c}_k(s)$  of  $c_k(s)$  the expression

$$\bar{c}_k(s) = \frac{1}{2} [\gamma_+(s) + \gamma_-(s)]. \quad (11)$$

Similarly, the approximation  $\bar{d}_k(s)$  of  $d_k(s)$  is taken as

$$\bar{d}_k(s) = \frac{1}{2j} [\gamma_+(s) - \gamma_-(s)]. \quad (12)$$

One can readily check that  $\bar{c}_k(s)$  and  $\bar{d}_k(s)$  are both ratios of real polynomials, the denominators being Hurwitz.

VI. REMARKS

The above approximation procedure leaves to the designer the major question of how many zeros should be retained in the approximating transfer function, and the minor question of how large a radius should be taken for the Butterworth circle. (This is minor since a suitably large radius is known to be satisfactory.) Rough guides in making these choices have been given above. But it is important to note that trial and error designs are perfectly feasible. This is because, using methods outlined in [6], one can always evaluate the performance of a suboptimal smoother. Consequently, if the performance is deemed unsatisfactorily far from optimum, one can increase the number of zeros.

(a)

(b)

Fig. 3. The zero pattern of (a)  $c_k(s) + jd_k(s)$  and (b)  $c_k(s) - jd_k(s)$ .

The authors have checked that the procedure works in the sense of not requiring inordinately many zeros on a number of examples, including the example given in Section VII.

VII. EXAMPLE

The original model is defined by

$$F = \begin{bmatrix} 0 & 1 \\ -2 & -2 \end{bmatrix}, G = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, H' = [1 \quad 0], Q = 1000, R = 1$$

and one obtains

$$\Sigma = \begin{bmatrix} 5.961 & 17.76 \\ 17.76 & 153.3 \end{bmatrix}, \bar{F} = \begin{bmatrix} -5.961 & 1 \\ -19.76 & -2 \end{bmatrix}.$$

Eigenvalues of  $\bar{F} = -\alpha \pm j\beta = -3.98 \pm j3.98$ .

Optimal fixed-lag error covariance with

$$\text{infinite } \Delta = \begin{bmatrix} 1.9827 & 0.00043 \\ 0.00043 & 62.812 \end{bmatrix}.$$

Optimal fixed-lag error covariance

$$\text{with } \Delta \text{ of } 0.5 = \begin{bmatrix} 2.014 & 0.0007 \\ 0.0007 & 63.18 \end{bmatrix}.$$

Note that  $\Delta$  is approximately twice the dominant time constant of the filter and almost all the improvement possible using smoothing is achieved with this  $\Delta$ . This is, in fact, an example of a general rule [10]. Note that in a multiple time constant system the dominant time constant can be thought of as the inverse of real part of the eigenvalue of  $\bar{F}$  which has smallest magnitude real part.

In any given case, however, actual calculations could be used to verify whether the possibility of achieving almost all possible smoothing improvement is achieved with a selected  $\Delta$ .

For the approximation, use two zeros for  $\gamma_+(s)$  and for  $\gamma_-(s)$  and a radius for the Butterworth circle of  $2\alpha$ . (This is the smallest number of zeros it is possible to use.) One can then calculate

$$\text{suboptimal fixed-lag error covariance} = \begin{bmatrix} 2.915 & 3.392 \\ 3.392 & 82.727 \end{bmatrix} \\ \text{with } \Delta \text{ of } 0.5$$

This should be compared with the optimal value and the filter error covariance; it is obvious that the error covariance is significantly reduced. Better and worse results are obtained for this problem by different suboptimal smoothers described in [6].

### VIII. CONCLUSIONS AND POSSIBLE FUTURE RESEARCH

Despite the difficulty of building optimal continuous-time fixed-lag smoothers, one can obtain good suboptimal smoothers in the stationary case. The design of these smoothers rests on the approximation of a matrix impulse response of finite support, as in (5). The key contribution of the paper is to explain a *straightforward* method for achieving the approximation. In practice, the quality of the approximation always needs to be checked, though there are heuristic guides as to the choice of the free parameters in the approximation procedure. Several questions suggest themselves.

1) In case the signal process is narrow band and bandpass, centered around  $f_c$  with bandwidth  $2f_b \ll f_c$ , the fixed lag to achieve significant improvement is approximately  $f_0^{-1}$  since the signal process can be thought of as arising from modulation of a carrier of frequency  $f_c$  by signal of bandwidth  $f_b$ . Thus, the dominant time constant is expected to be of the order of  $f_0^{-1}$ , while the smoother bandwidth is approximately  $f_c$ . The delay-bandwidth product is accordingly a very large number, and such a smoother is extremely difficult to implement. An alternative approach is needed—perhaps involving bandpass to low-pass transformation.

2) There are some situations in which optimal nonlinear filters can sometimes be effectively replaced by suboptimal linear filters, e.g., in high signal-to-noise ratio FM demodulation. The question then needs to be answered as to whether linear smoother design ideas such as those of this paper could be effectively applied. The question could, in the first instance, be tackled with simulation and the use of the heuristic type of arguments often used for discussing FM demodulation in elementary communication systems textbooks.

3) There is an alternative to the smoothing formula (4) of the form

$$\hat{x}(t|t+\Delta) = A\hat{x}(t+\Delta|t+\Delta) + \int_t^{t+\Delta} B(t+\Delta-\tau)\hat{x}(\tau|\tau) d\tau. \quad (11)$$

This formula is derived in [9]. One could seek to approximate the impulse response  $B(\cdot)$  (zero outside  $[0, \Delta]$ ) and compare the effectiveness of smoother approximations obtained this way. It is clearly advantageous that no delay here is required. It may also turn out that the approximants can be kept less complex, particularly since they are driven by a band-limited process  $\hat{x}(\cdot|t)$  [in contrast to the approximants derived earlier, which are driven by a white process  $v(\cdot)$ ]. The fact that the input is band-limited means that there are fewer stringent requirements on the accuracy of the approximation at higher frequencies.

We are aware of the existence of the unpublished work of P. Hedelin on even more straightforward approaches to the design of suboptimal smoothers. The smoothers obtained for many examples with scalar measurement processes offer strikingly good performance; there may be some difficulty in obtaining such excellent results for vector measurement processes.
