Abstract

This paper describes the implementation of behaviour for real-time visual servoing on a mobile robot. The behaviour is a component of a multi-robot cleaning system developed in the context of our investigation into architectures for cooperative systems. An important feature for support of cooperation is the awareness of one robot by another, which this behaviour realises. Robust feature tracking aided by a hardware vision system is described. This forms the basis for range and pose estimation using a 3D projective model.

1. INTRODUCTION

As part of our research into behaviour architectures for cooperative multi-robot systems, we are constructing a cleaning system using two autonomous mobile robots [Jung 97]. There are numerous component behaviours implemented to support the basic cleaning task. Among them is the requirement for one robot to be aware of the other. This is realised by visual tracking, and estimating the range and pose, of the robot in its field of view in real-time. This paper briefly describes the cleaning task, but is primarily a description of the implementation of the visual servoing behaviour.

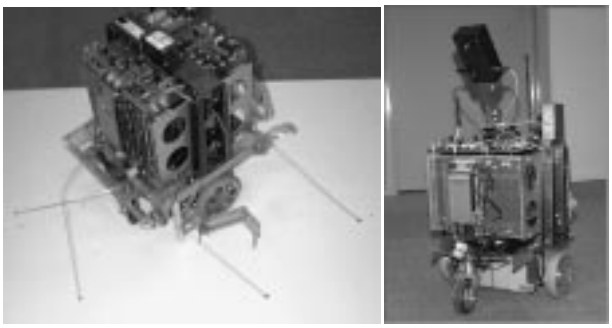

Figure 1 - Yamabicos Flo and Joh

2. COOPERATION

Research into multi-robot systems is driven by the assumption that multiple agents have the possibility to solve problems more efficiently than a single agent does. Agents must therefore cooperate in some way. There are many tasks for which a single complex robot could be engineered; however, in many cases there are advantages to using multiple robots. A multi-robot system can be more robust because the failure of a single robot may only cause partial degradation of task performance. In addition, the robots can be less complex since each is only responsible for partial fulfilment of the task. Our philosophy is to design heterogeneous multi-robot systems where appropriate.

Cooperation has been intensively studied in the robotics community recently, particularly the cooperation observed in eusocial insect societies, such as ants (see [Kube 94][Mataric 95][Steels 90]). This type of cooperation has been termed *collective robotics* and is characterised by homogeneity of the agents and *emergent* behaviour.

The robotics literature usually reserves the term *cooperation* for cases where explicit communication is involved – which implies autobiographical agents. This greatly increases the possibilities for types of cooperative behaviour. Much research has been reported where robots communicate. Some systems utilise central control, others use complex negotiation schemes between agents, and yet others some combination of both [Kuniyoshi 94] [Noreilis 92][Parker 95].

The behaviour architecture we have developed for distributed planning, ABBA, supports all the above mentioned paradigms [Jung 97b]. However, we are particularly interested in heterogeneous agents that have identity, the capability to communicate, and can jointly plan cooperative behaviour without central control. Since the robots have identity, awareness of one robot by another can play a major role in these cooperative systems, and has been investigated in the literature [Parker 95]. This provides the motivation for implementing the capability for one robot to visually detect, recognise, track, and servo on another robot. The task we have implemented utilises this behaviour by design.

The remainder of this paper discusses the implementation of this visual behaviour in a task context.

2.1 Multi-robot Cleaning

We have chosen to implement cooperative cleaning of our laboratory floor. The 'Yamabico' robots [Yuta 91] shown in Figure 1 are heterogeneous in the sense that each has different tools and sensors such that neither can accomplish the task alone.

One of the robots, *'Joh'*, has a software-controlled vacuum cleaner. Joh's task is to vacuum piles of litter from the laboratory floor. It cannot vacuum close to walls or furniture. It has the capability to 'see' piles of litter using a CCD camera and a video transmitter that sends video to the *Fujitsu MEP tracking vision system*. The vision system is capable of landmark-based navigation and collision avoidance [Cheng 96]. The vision system communicates with the robot over a pair of radio modems.

The other robot *'Flo'*, has a brush tool that is dragged over the floor to sweep distributed litter into larger piles for Joh to pick up. It navigates around the perimeter of the laboratory where Joh cannot vacuum and deposits the litter on open floor space. Its primary sensors are four proportional whiskers developed specifically for wall following and perimeter navigation [Jung 96a]. The task is to be performed in the laboratory environment – robots have to contend with furniture, other robots, people, opening doors, changing lighting conditions and other hazards.

3. VISUAL TRACKING

One implementation of the cleaning task involves Joh waiting until Flo is in its field of view, and then visually servoing on Flo until Flo dumps a pile of litter in the vicinity. This requires not only robust tracking for servoing while Flo is in view, but also the ability to continuously determine if Flo in the image. This section details how this is achieved. First, a look at our vision system.

3.1 The Fujitsu vision system

The Fujitsu MEP template tracking vision system consists of a VME video card, tracking card and a 68040 CPU card for processing. The tracking module uses a correlation chip for correlating stored templates to an NTSC video stream (30Hz). The correlations occur after the video module has digitised a frame, and hence the results are always a frame behind the video stream.

The tracking card is provided with up to 100 8×8 or 16×16 templates to be correlated in specified search areas for each in the coming frame. The search areas are divided into a 16×16 grid since the tracking module performs 256 correlations per template in each search area. The tracking module performs a correlation calculation between a template and all possible offsets that move it within its search area. The system also supports horizontal and vertical magnification in templates, so that the template pixels are compared with every n^{th} image pixel – where n is the x or y magnification (m_x or m_y). If o_x and o_y are the offsets of the template in the image, and g_t and g_f are the template and images respectively, then the correlation calculation is simply the sum of pixel differences as given by (1).

$$D = \sum_{x=0}^{Size}\sum_{y=0}^{Size} \left| g_t(x_t, y_t) - g_f(x_f, y_f) \right| \qquad (1)$$

$$\text{where} \quad x_t = x \cdot m_x \qquad y_t = y \cdot m_y$$

$$x_f = x \cdot m_x + o_x \qquad y_f = y \cdot m_y + o_y$$

The result is a vector for each template that corresponds to the offset from the search area centre where the best correlation between the template and image was found.

By moving the centre of the search area based on these result vectors a template can be crudely tracked. Any change in brightness, occlusion, or change in size – caused by changes in range, will result in loss of tracking.

3.2 What do we track?

Since the target of our tracking is artificial – Flo, we have control over its appearance. Hence, we chose to put the geometric pattern shown below on both sides of the robot (the thick black rectangle is the pattern, the other lines are graphics).

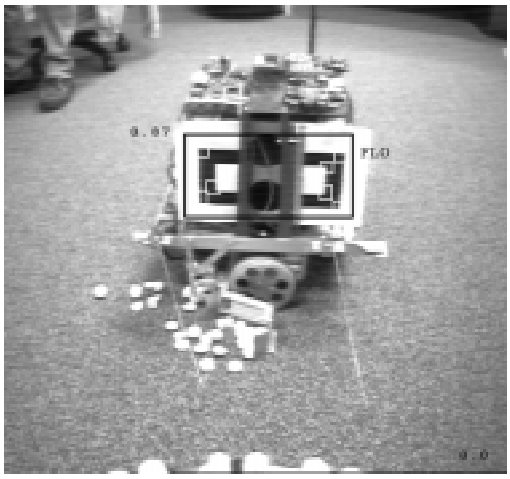

Figure 2 - Flo's side as seen from Joh's CCD camera

The pattern is a hollow rectangle with very thick sides, designed such that templates of the inner and outer corners will be scale invariant. A problem arose due to the motion involved – since the video signal is interlaced, motion causes one field to be displaced with respect to the other. This gives very bad correlation with the template and tracking is lost. The solution was to use templates with a magnification of two, so that only every other vertical line is used for matching.

The task dictates that Flo will almost always been seen from the side. Specifically Flo spends most of its time

sweeping against walls, which Joh's behaviour keeps it away from. It is sufficient for Joh to detect this pattern to 'see' Flo. Using this method we want something that detects the robot irrespective of the range or pose of the pattern.

3.3 Utilising geometric constraints

Tracking the ten templates independently – eight of the inner and outer corners, as well as two side templates, is not sufficient for tracking. The templates are quickly lost by the tracking system due to variations in brightness and changes in shape due to viewing the pattern at an oblique angle. The tracking can be made robust by utilising geometric constraints between template positions.

Our first implementation modelled the pattern as a 2D rectangle in which the size was allowed to vary. Hence, if we know the position of any two corners, the positions of the other templates are also known. Unfortunately, because the tracking is noisy we can never know for certain if we have the coordinates of any particular corner. However, we do have a measure of the uncertainty of any particular match – the correlation value of the best match returned by the tracking module. The method developed to use the noisy tracking positions with their correlation values, and the predictions from the 2D model, was a network of independent Kalman filters. The scheme was first developed in our laboratory to track features on a human face for gesture recognition [Heinzmann 97].

The Kalman filter is a recursive linear estimator, which merges two independent measurements of a quantity with known measurement error to give the optimal estimate of the value and associated error [Boznic 86]. The use of Kalman filtering in feature tracking has previously been reported by McLaughlan *et al.* [McLauchlan 94]. Our approach also uses a Kalman filter for each feature, but it also uses the information from all other features.

The Kalman filter takes two measurements of a feature position and their associated errors as input, and gives a new optimal estimate of the position. The first measurement comes from the tracking module. If we let $\overline{fp_i}(t-1)$ denote the estimated feature position of feature *i* from the previous frame, and $\overline{m_i}$ the displacement from the search area centre to the new best template match for the feature, then the measurement becomes (2).

$$\overline{mp_i}(t) = \overline{fp_i}(t-1) + \overline{m_i}(t) \tag{2}$$

Now, the second 'measurement' comes from the 2D model of the rectangle. The predicted position of feature *i*, $\overline{pp_i}$ in this case, uses the displacements between features according to the model. This displacement vector between *i* and *j* is $\overline{d_{ij}}$. The prediction of the position of the feature proceeds as follows. All features are iterated over, and in each case its position in the previous frame $\overline{fp_j}(t-1)$ has the displacement between it and feature *i* subtracted from it. This gives an estimate of the position of feature *i* according to the model and the last position of feature *j*. This term is weighted by the certainty in the position of feature *j*, and the terms are summed for all *j* (including *i=j*). After re-normalising the effects of the weights, we have an estimate of the position of feature *i* according to the model and a weighted contribution of all the other features. Equation (3) shows the formulation, where *P* is the variance.

$$\overline{pp_i}(t) = \frac{\sum_j \frac{\overline{fp_j}(t-1) - \overline{d_{ij}}(t-1)}{P_j(t-1)}}{\sum_j \frac{1}{P_j(t-1)}} + \overline{m}(t) \tag{3}$$

Here $\overline{m}$ is the gross motion of the whole set of features, again weighed by the variances, from the vision module. It is added to the predicted position of the feature as a prediction of future motion. This assumes that the motion of the whole feature set – ie. the object being tracked – exhibits roughly linear motion. The acceleration effects are very small from one video frame to the next except for unrealistic accelerations. The calculation for $\overline{m}$ follows.

$$\overline{m}(t) = \frac{\sum_{i=1}^{n} \frac{\overline{m_i}(t)}{P_i(t-1)}}{\sum_{i=1}^{n} \frac{1}{P_i(t-1)}} \tag{4}$$

The predicted position variance is calculated analogously. Now we have the 'measurements' from the tracking module $\overline{mp_i}$ and from the model $\overline{pp_i}$ for each feature.

Next we use the Kalman filter to obtain the new estimate of the feature position.

$$\overline{fp_i}(t) = \overline{pp_i}(t) + K_i(t)\left(\overline{mp_i}(t) - \overline{pp_i}(t)\right) \tag{5}$$

All that remains is to calculate new search areas for the matching in the next frame. Then the process is iterated again. All of this calculation is performed at frame-rate on the 68040 CPU. There is also a low priority process, which sweeps search areas over the entire image looking for a better match for each feature than the current best match. This is to allow the re-acquisition of tracking if it is completely lost due to occlusion.

Using this technique with a 2D sizeable rectangular model the tracking is very robust to changes in range. It is also moderately robust to changes in the angle between rectangle and the plane of the camera. Variations in brightness caused by the automatic shutter speed adjustment on our camera can also be compensated for. We match a number of templates of various brightness at the same position for a given feature.

4. RANGE AND POSE ESTIMATION

To satisfy the requirements of the cleaning task Joh must be able to determine Flo's range and pose. In one experiment Joh notifies Flo when Flo has been visually acquired. Flo notes its position and may later communicate the location of a litter pile for Joh to vacuum using coordinates relative to this location. Hence Joh needs Flo's position and heading to know the coordinate reference frame. Since Joh can identify piles of litter visually once in the vicinity, high accuracy was not required.

4.1 A First Cut

Our first implementation was very simple. We observed that since the camera is inclined toward the floor, the range to Flo is proportional to the height of its pattern in the image. So a rough calibration provided a simple measure of range. We also noted that due to perspective foreshortening, one side of the rectangle becomes smaller with respect to the other, in proportion to the angle of inclination to the camera plane.

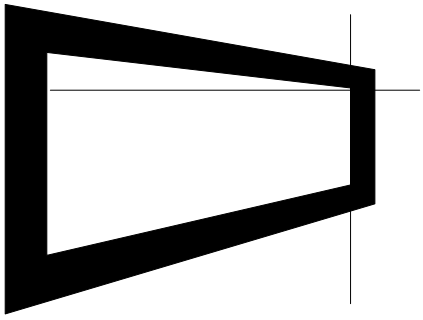

Figure 3 - Perspective foreshortening

The ratio of these two sides gives a measure of the inclination angle. Although this mechanism works, unfortunately is was not accurate enough for our needs. There are a number of problems. First, because the model used for tracking is a 2D rectangle, it is working against predicting the correct feature positions for the corners if the angle is great, as can be seen from Figure 3. Also in this situation, the image of the corners themselves is no longer a right angle. The templates used for tracking all the corners are right angled. Hence tracking is easily lost when Flo is inclined over 40^o out of the camera plane. This error has a large effect when use to project Flo's relative coordinate specifications of litter piles.

Clearly we needed a 3D model to track robustly in the situation when perspective foreshortening becomes significant. Much research has been conducted on recovering 3D-pose information given 2D projections, but in most cases, for full recovery of points, weak-perspective projection is assumed [Alter 92][Grimson 92]. A weak perspective, or affine, projection is orthographic projection plus scaling. This essentially ignores perspective foreshortening by assuming all 3D points are roughly the same distance from the camera. Hence we require full perspective projection.

4.2 Inverse Projective Geometry

The 3D model includes the 3D coordinates of the outside corner points on the rectangular pattern. We need to be able to determine these 3D locations from the 2D positions in image space. We also need to be able to re-project the 3D locations onto the feature positions in image space during tracking. Hence, we need the projective transformation matrix of the camera.

A projective transformation has eight parameters. There are a number of constraints we can take advantage of. We know the absolute size of the pattern. We also know that the pattern moves only in a plane inclined to the camera. This is because as the robot moves along the floor plane, which is inclined to the camera at a fixed angle, the height of the pattern from the floor doesn't change. In addition the pattern only rotates about one axis (perpendicular to the floor) – the robot does not tilt to one side. These two constraints imply that the 3D orientation of the lines on the left and right side of the pattern doesn't change.

Calibration

We need to know the height of the robot's camera from the floor plane in which the other robot moves, and the angular tilt forward. Because this is only a translation and a rotation about one axis, the value can be recovered from the camera projection matrix. This can be obtained by a calibration procedure. Flo is placed at a known distance in front of the camera and the pattern aligned with the camera image plane. Now we know the absolute positions in 3D of the corner points, and using the tracking with a simple 2D rectangular model, we can also obtain the image projection of each corner. These four 3D points and their corresponding projections can uniquely define the matrix. If t_{ij} are the elements of the 3×3 projection matrix T, and the four corner points are $(\lambda_i x_i, \lambda_i y_i, \lambda_i)^t = T(X_i, Y_i, 1)^t$, then the system below is solved [Kapur 85].

$$\begin{bmatrix} X_1 & Y_1 & 1 & 0 & 0 & 0 & -x_1X_1 & -x_1Y_1 \\ 0 & 0 & 0 & X_1 & Y_1 & 1 & -y_1X_1 & -y_1Y_1 \\ X_2 & Y_2 & 1 & 0 & 0 & 0 & -x_2X_2 & -x_2Y_2 \\ 0 & 0 & 0 & X_2 & Y_2 & 1 & -y_2X_2 & -y_2Y_2 \\ X_3 & Y_3 & 1 & 0 & 0 & 0 & -x_3X_3 & -x_3Y_3 \\ 0 & 0 & 0 & X_3 & Y_3 & 1 & -y_3X_3 & -y_3Y_3 \\ X_4 & Y_4 & 1 & 0 & 0 & 0 & -x_4X_4 & -x_4Y_4 \\ 0 & 0 & 0 & X_4 & Y_4 & 1 & -y_4X_4 & -y_4Y_4 \end{bmatrix} \begin{bmatrix} t_{11} \\ t_{12} \\ t_{13} \\ t_{21} \\ t_{22} \\ t_{23} \\ t_{31} \\ t_{32} \end{bmatrix} = \begin{bmatrix} x_1 \\ y_1 \\ x_2 \\ y_2 \\ x_3 \\ y_3 \\ x_4 \\ y_4 \end{bmatrix} \quad (6)$$

Where t_{33}=1. This process is performed only once. This projection matrix T is used to perform the forward projection from the 3D model points to the image space during tracking – to predict the feature locations.

From 2D to 3D

Consider the line joining the top and bottom corners of one side of the rectangular pattern. This is a line of known length, and known direction – it always runs perpendicular to the floor. Let the projected image end points of this line, which are available from the tracked feature positions, be $(u_1, v_1)^t$ and $(u_2, v_2)^t$, and the 3D line $(a,b,c)^t + \rho(m_1, m_2, m_3)^t$. Then, since we know the direction cosines $(m_1, m_2, m_3)^t$ and the length ρ, the solution for both end-points can be calculated from (7) [Haralick 93].

$$c = \frac{\rho[(u_2 - u_1)(fm_1 - u_2 m_3) + (v_2 - v_1)(fm_2 - v_2 m_3)]}{(u_2 - u_1)^2 + (v_1 - v_2)^2} \quad (7)$$

$$a = \frac{u_1}{f} c \qquad b = \frac{v_1}{f} c$$

Where *f* is the known focal length of the camera.

So performing this calculation on the lines from both the left and right of the pattern gives us all the corner locations in 3D. These points are in the camera coordinate system, which has its origin at image centre and z-axis perpendicular to the image plane. So to calculate the range, bearing and heading to Flo we need to transform this to 'floor' coordinates. A translation and rotation, by amounts calculated from the camera projection matrix, easily achieve this since we know the pattern plane is perpendicular to the floor plane.

All together now

In summary, the tracked feature positions of the four corners are used in pairs in equation (7) to determine their 3D positions. These positions are passed through the camera projection matrix *T* and used to update the positions of the features during the next tracking frame. These same points are also transformed into 'floor' coordinates where some simple trigonometry can determine the range from Joh, the bearing angle in relation Joh, and the heading angle relative to the camera plane. This is possible because the forward tilt and height of the camera in relation to the floor can be calculated from the calibrated matrix *T*. These three values are then used to calculate Flo's trajectory. The trajectory is used both to visually servo on Flo by sending motion commands to Joh from the vision system via a radio modem, and also as a reference frame for litter pile location specifications communicated by Flo to Joh.

5. EXPERIMENTAL RESULTS

The sequence of frames in Figure 4 was taken from video footage of Joh visually servoing on Flo while Flo comes past 'sweeping' litter from against a wall.

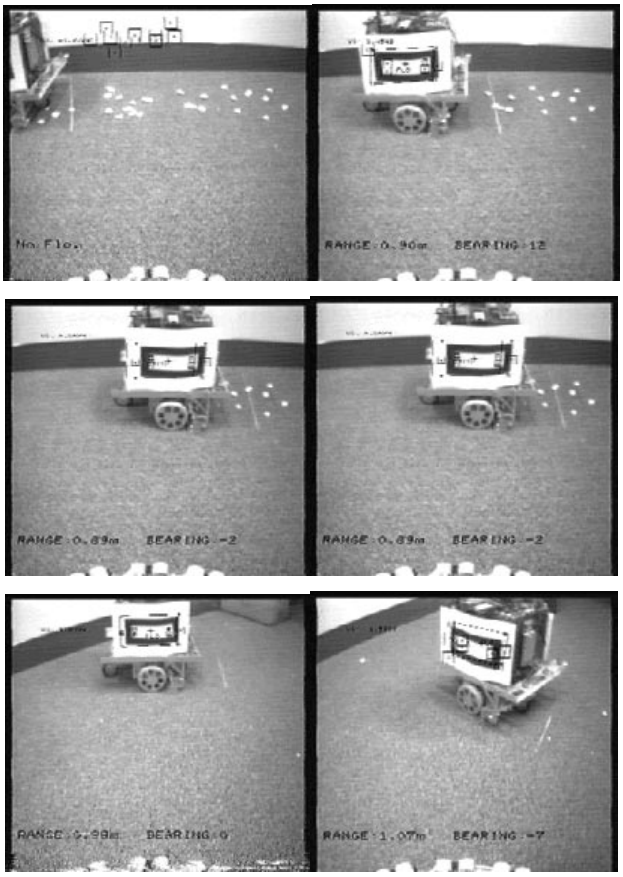

Figure 4 - Visual servoing (with range and bearing)

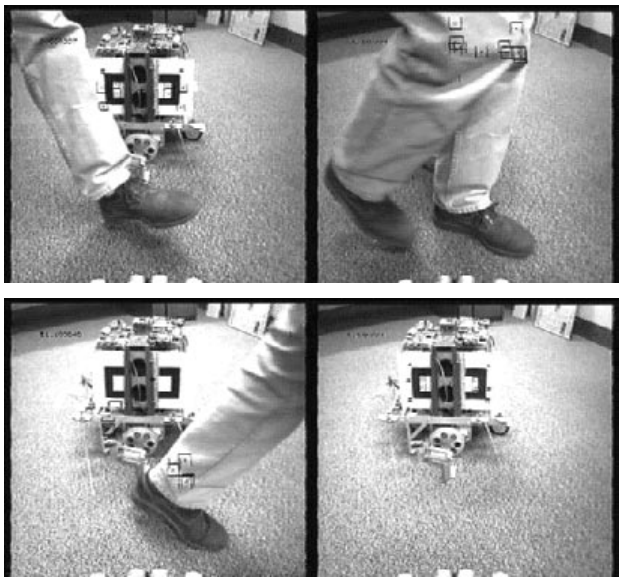

Figure 5 - Loss and re-acquisition of tracking

The view is from the vision system video stream with overlay graphics. The graphics is sometimes difficult to see because of interlacing effects. The small black boxes near the corners of the pattern represent where the features

are matched. The larger the box the poorer the match, so a very good match gives small spots. The frames from Figure 5 show how tracking is re-acquired after being lost due to occlusion. The 3D model was required because it gives better predictions of feature positions by taking into account perspective foreshortening. This is important because slight variations in the vertical spacing of the left and right corners of the pattern are crucial for estimating the heading when the angle relative to the camera plane is small. The algorithm can easily distinguish between 0^o and 10^o out of the camera plane – which translates to less than a 20cm error in the litter pile position at 1m – well within Joh's visual field of view. This video footage is available in *mpeg* format from our web page.

6. CONCLUSION

The method presented for tracking and calculating range, heading and bearing estimates on a known moving target provides the accuracy we require to support our cooperative behaviour. The method also requires little calculation – mostly addition and multiplication, but some trigonometric functions. This allows the calculation to be performed in real-time. This economy of calculation is largely due to the exploitation of many geometric constraints available for this particular problem.
